Jordan trees at the same level of the tree lie within disjoint horizontal strips, we can use the right vertical line to attach together all the Jordan trees stored on the same level. For example, it suffices to connect the rightmost point of each Jordan tree to the vertical line. This gives us a single Jordan tree for each level in  $\mathcal{T}$ . Let  $T_1, \dots, T_k$  be the sequence of these Jordan trees given by increasing tree height;  $k = O(\log p)$ .

Unfortunately, these trees might intersect one another. Because of the interval tree construction, however, the only possible intersections must occur between a connecting (i.e., horizontal) edge of a tree  $T_i$  and an edge of  $T_j$ , for  $j > i$ . To remove these intersections we proceed as follows: First, we compute the visibility map of each Jordan tree  $T_j$  separately [1] and preprocess it for fast point location [4, 10]. This allows us to shoot a ray from the left endpoint  $a$  of a connecting edge  $ab$  of  $T_i$  towards any  $T_j$  ( $j > i$ ) in  $O(\log n)$  time. If a hit  $c$  occurs within  $ab$ , then we call  $c$  a “candidate.” Among all the Jordan trees  $T_j$  ( $j > i$ ), we identify the leftmost candidate  $c$ , and if it exists, we replace  $ab$  by  $ac$ . Otherwise, we leave the connecting edge  $ab$  as is. We follow the same procedure for all the connecting edges of the Jordan trees  $T_1, \dots, T_{k-1}$ , which takes a total of  $O(n + p(\log p) \log n)$  time.

We claim that the resulting graph is a valid visibility tree for  $P$ . Because of the ray-shooting strategy no proper intersections are created, so it suffices to show that the graph is connected and acyclic. We establish this by induction on the number of nodes in  $\mathcal{T}$ . The case of a single node is obvious: the graph is the Jordan tree of a collection of Jordan chains intersecting the same horizontal line, with in addition an edge connecting it to the infinite vertical line.

Assume now that  $\mathcal{T}$  has more than one node. Pick a leaf  $v$  and denote by  $\ell_v$  the horizontal line associated with it. Let  $C_1, \dots, C_m$  be the Jordan chains at  $v$  sorted by increasing order of their rightmost intersections  $r_1, \dots, r_m$  with  $\ell_v$ . To complete the induction, it suffices to show that no cycle can pass through any of the  $C_i$  (acyclicity) and that the  $C_i$ 's are in the same connected component as the other chains (connectivity). This is easily established by induction on  $m$ . The key observation is that the only rays shot towards  $C_i$  emanate from the points  $r_j$  for  $j < i$ . This shows, in particular, that no ray can hit  $C_1$ . Exactly one ray is shot from  $C_i$ , namely, the one shot from its rightmost point  $r_i$ . These last two facts prove that no cycle can be part of  $C_1$  and that this chain is connected to the rest of the graph. We remove  $C_1$  along with the connecting edge emanating from  $r_1$ , which leaves us with  $m - 1$  chains. This reasoning takes care of both the basis ( $m = 1$ ) and the inductive step.

We can save time by reducing the number of point locations. Conceptually the previous algorithm can be modeled as follows. For each  $i$  ( $0 \leq i < k$ ) we are given  $p_i$  points which we must locate in the visibility maps of  $T_{i+1}, \dots, T_k$ . Each point location requires  $O(\log n)$  time and  $\sum p_i = p$ . In addition, we have the possibility of merging several  $T_i$ 's together and computing a point location structure for the resulting visibility map. Consider a balanced tree of degree  $d$  whose leaves are associated with  $T_1, \dots, T_k$  from left to right. Each internal node contains the visibility map (preprocessed for point location) of the union of the  $T_i$ 's stored at the leaves below. Let  $n_v$  and  $p_v$  be the total number of vertices and chains, respectively, associated with the leaves below node  $v$ . If all the information stored at the children of  $v$  is already available, it takes  $O(n_v + p_v d \log n)$  time to compute and preprocess the visibility map at  $v$ .

Therefore, computing the visibility map at the root (which is our ultimate goal) takes time  $O((n + pd \log n) \log_d k)$ . Since  $k = O(\log p)$ , setting  $d = k^\epsilon$ , for any fixed  $\epsilon > 0$ , gives  $O(n + p(\log n)^{1+\epsilon})$ , which is also  $O(n + p(\log p)^{1+\epsilon})$ . Setting  $d = 2$  gives  $O((n + p \log p) \log \log p)$ . It is a trivial exercise to show that  $\Omega(n + p \log p)$  is a lower bound on the time required to

is easy to see that this result is optimal.

We briefly review the linear algorithm of [9] and modify it to deal with several curves at once. We assume the reader’s familiarity with [9]. The line  $\ell$  breaks up the curve  $C$  into disjoint arcs entirely below or above the line. The arcs above (resp. below) the line form a parenthesis system which can be represented by a tree  $T_a$  (resp.  $T_b$ ), as indicated in Figure 2.2. Each node represents an arc and its children correspond to the arcs directly nested within it. The left-to-right order of the child arcs are encoded in a finger tree (see also [14]). The basic idea of the algorithm is to trace the curve and build  $T_a$  and  $T_b$  incrementally along the way. As the curve crosses  $\ell$  and is about to enter, say, the top halfplane, we already know what arc  $\alpha$  above  $\ell$  “covers” the new arc  $\beta$  to be inserted. Let  $\alpha_1, \dots, \alpha_k$  be the child arcs of  $\alpha$ : we must identify the interval of arcs  $[\alpha_i \dots \alpha_j]$  that  $\beta$  covers ( $\alpha_2$  and  $\alpha_3$  in the case of Figure 3), which we do by searching through the finger tree for the child arcs of  $\alpha$ . Once the search is completed, we must update the tree  $T_a$  and the finger trees associated with the children of  $\alpha$  and  $\beta$ . By keeping pointers between matching features in  $T_a$  and  $T_b$ , we can gain access to a finger in constant time and thus readily jump between the two trees. An amortized analysis shows that the whole algorithm runs in linear time.

Let us now consider the case of a collection of disjoint Jordan curves. First, we sort the curves by their leftmost intersections with  $\ell$  and break each curve at that point, which produces at most  $2p$  Jordan curves. We process each curve one by one as indicated above, retaining the current  $T_a$  and  $T_b$  as we switch from one curve to the next. We process the curves in reverse order, i.e., we begin with the curve whose leftmost point is rightmost (breaking ties arbitrarily). The only point that remains to be clarified is how we locate the first point  $x$  of the next curve to be processed. To do that, we simply go back to the first point of the curve previously inserted and then traverse the current sorted list of intersections to the left until we reach  $x$ . The overhead of these traversals is at most linear, so we can “pretend” in the amortized analysis that we are sorting a single curve, and the same time bound of  $O(n)$  readily follows. Since we have to sort  $p$  numbers initially, the total running time is  $O(n + p \log p)$ .

Note that we can connect the  $p$  curves together by adding well chosen segments along  $\ell$ : specifically, we connect the rightmost intersection of each curve to its successor (if it has one) in the sorted list of intersections (Figure 4). This obviously produces a plane tree, which we call a *Jordan tree*. Thus, in a total of  $O(n + p \log p)$  time, we have connected all the curves into a single tree without creating any intersections. The horizontal segments added for the connections are called the *connecting edges* of the Jordan tree.

### 3 Connecting Jordan Curves Together

Let  $P$  be a collection of  $p$  disjoint Jordan (polygonal) chains with a total of  $n$  vertices. For convenience we assume that no two vertices share the same coordinates. Let  $\mathcal{T}$  be the interval tree [12] defined over the  $y$ -extents of the chains. We briefly recall how  $\mathcal{T}$  is computed. Consider the  $p$  intervals formed by the projections of the chains onto the  $y$ -axis. Let  $\ell$  be the horizontal line whose height is the median among the  $y$ -coordinates of the intervals’ endpoints. Associate the root of  $\mathcal{T}$  with  $\ell$  and the subset of chains that intersect  $\ell$ . The left (resp. right) subtree of the root is defined in the same manner with respect to the set of chains entirely above (resp. below) the line  $\ell$ . It is elementary to construct  $\mathcal{T}$  in  $O(n + p \log p)$  time.

Note that the chains associated with any node  $v$  of  $\mathcal{T}$  all cut through the same horizontal line  $\ell_v$ . Thus, we can apply the generalized form of Jordan sorting described in the previous section to create a single Jordan tree connecting together all the chains at  $v$ . Since any two

# 1 Introduction

Simple polygons are arguably the most popular objects in computational geometry. As the elementary constituents of the discretized modeling of two-dimensional scenes, they occur naturally in computer graphics, vision, robotics, VLSI, numerical analysis, etc. Little can be done efficiently, however, unless the polygons are triangulated [7], so a considerable amount of attention has been given to polygon triangulation over the years, e.g., [1, 2, 3, 4, 5, 6, 8, 11, 14]. In particular, Chazelle has shown that a simple polygon can be triangulated in linear time [1].

Often we have to deal with not just one but a whole collection of disjoint simple polygons, or more generally, Jordan chains (i.e., non self-intersecting polygonal curves). For example, a polygon might have holes, or in the case of motion planning, a robot might be moving in a room with several polygonal obstacles, or we might be faced with a set of disjoint polygons as appearing in one layer of a VLSI mask. To triangulate a collection of disjoint Jordan chains, we add line segments so as to merge them into a single connected planar graph, which we can then triangulate in linear time. For this we use the observation that a connected planar graph with straightline edges and no self-intersections can be regarded as a simple polygon by embedding it on a sphere and making a “thickening” of its edges the outside of the polygon.

In keeping with standard practice we do not work on triangulations directly but, instead, on visibility maps. A triangulation of a set  $P$  of disjoint Jordan chains is obtained by a maximal addition of non-intersecting line segments joining vertices of the chains. The *visibility map* of  $P$ , on the other hand, is the planar map obtained by extending two horizontal segments from each vertex, one in each direction, until each of them hits one of the chains, if at all. As is well-known [2, 5] a triangulation can be derived from the visibility map in linear time.

Let  $P$  be a collection of  $p$  disjoint Jordan chains  $C_1, \dots, C_p$ , with a total of  $n$  vertices. We define a *visibility tree* for  $P$  as follows: first, draw an infinite vertical line to the right of all the chains. Then, for each chain  $C_i$  in turn, pick a point in  $C_i$  and draw a ray to the right until it hits either some  $C_j$  or the vertical line, and add the point hit as a new vertex. If we choose the origin of the rays carefully we can ensure that the resulting planar graph is connected and acyclic: in that case it is called a visibility tree for  $P$  (Figure 1).

We give an algorithm for computing a visibility tree for  $P$  in time  $O(n + p(\log p)^{1+\varepsilon})$ , for any fixed  $\varepsilon > 0$ . A variant of the method runs in time  $O((n + p \log p) \log \log p)$ . The complexity of these algorithms comes close to the lower bound of  $\Omega(n + p \log p)$  known for that problem. Note that with a visibility tree in hand, we can compute the complete visibility map of  $P$ , and from there, a triangulation of  $P$  in linear time [1]. Seidel [13] has given a probabilistic algorithm for triangulating disjoint Jordan chains with an expected running time of  $O(n \log^* n + p \log p)$ . His algorithm outperforms ours only if  $p$  is very close to  $n$ . Furthermore, our solution is deterministic. The approach we follow combines a generalized form of Jordan sorting [9] (which is interesting in its own right) with the efficient use of fast point location [4, 10] and interval trees [12].

## 2 Generalized Jordan Sorting

Let  $x_1, \dots, x_n$  be the intersections of an oriented Jordan curve  $C$  with a horizontal line  $\ell$ , given in the order they occur along the curve (Figure 2.1). Jordan sorting is the problem of sorting the coordinates  $x_i$ : for this, a linear-time algorithm was proposed by Hoffmann et al. [9] We extend their result in the following manner. Given a collection of  $p$  disjoint Jordan curves with a total of  $n$  intersections with  $\ell$ , sort the intersections along  $\ell$  in time  $O(n + p \log p)$ . It

## Abstract

Recent advances on polygon triangulation have yielded efficient algorithms for a large number of problems dealing with a single simple polygon. If the input consists of several disjoint polygons, however, it is often desirable to merge them in preprocessing so as to produce a single polygon that retain the geometric characteristics of its individual components. We give an efficient method for doing so, which combines a generalized form of Jordan sorting with the efficient use of point location and interval trees. As a corollary, we are able to triangulate a collection of  $p$  disjoint Jordan polygonal chains in time  $O(n + p(\log p)^{1+\epsilon})$ , for any fixed  $\epsilon > 0$ . A variant of the algorithm gives a running time of  $O((n + p \log p) \log \log p)$ . The performance of these solutions approaches the lower bound of  $\Omega(n + p \log p)$ .
